## 4 ANIMAL BONES: DATA by Andy Hammon

### 4.1 Appendix 1: methods

## Taxonomic identification

All specimens were identified to species or taxonomic group where possible. Ribs and vertebrae (excluding the axis and atlas) and unidentifiable specimens were assigned to size class (large/medium). The English Heritage vertebrate skeleton reference collection (held at Fort Cumberland, Portsmouth) was used for identification purposes in addition to published criteria (see below).

## Sheep/goat

The distinction between sheep (Ovis aries) and goat (Capra hircus) was attempted on the mandibular third and fourth deciduous premolars using the criteria of Payne (1985) and on the permanent dentition when in situ using the criteria of Halstead et al. (2002). Distinction of the following elements was attempted using a combination of Boessneck (1969) and Prummel and Frisch (1986): horncore, humerus, radius, ulna, metacarpal, tibia, astragalus, calcaneum and metatarsal. Additionally, the criteria of Kratochvil (1969) was used for the distal tibia.

## Pig/wild boar

Metrical data for the mandibular teeth and distal humerus were used to distinguish between domestic pig and its progenitor wild boar (Sus scrofa) following Payne and Bull (1988).

## Equids

Species distinction was attempted on the maxillary and mandibular dentition when in situ using the criteria of Davis (1987b, 1980), primarily in the effort to separate horse (Equus caballus) from donkey (E. asinus).

## Red/fallow deer

The distinction between red deer (Cervus elaphus) and fallow deer (Dama dama) was attempted on all elements using the criteria of Lister (1996).

## Lagomorphs

The distinction between hare (Lepus sp.) and rabbit (Oryctolagus cuniculus) was attempted on all elements using the criteria of Callou (1997).

## Domestic fowl

The distinction between chicken (Gallus gallus) and the closely related species of Guinea fowl (Numida meleagris) and pheasant (Phasianus colchicus) was attempted on the following elements using the criteria of Albarella (pers. comm.) and MacDonald (1992): scapula, carpometacarpus, femur and tarsometatarsus.

## Recording

Identified or classified (rib and vertebrae) fragments were recorded on a Microsoft Access XP database. Each fragment was given an identification number and the following information was recorded: site code; context number; taxa/taxonomic group; skeletal element; side; presence/absence of bone zone (see below); mandibular tooth eruption and wear; post-cranial epiphyseal proximal and distal fusion; whether foetal/neonatal or juvenile; and articulation with other specimens. In addition, other variables were recorded relating taphonomy and biometry (see below).

## Taphonomy

The recovery method, state of surface preservation, presence/absence of root etching, angularity of breaks, gnawing, burning and completeness were all recorded. The type of burning was recorded because it provides a crude measure of temperature and may indicate cooking or disposal method. The type and location of butchery was recorded, the latter using Serjeantson's (1996, 195-200) zones. This will be especially useful when assessing diachronic butchery patterns and in discussions regarding the acculturation of the indigenous population.

## Quantification

Three methods of quantification were used to compare the frequencies of the main taxa/taxonomic groups. These methods mirror those used in the earlier reports to make results directly comparable between the hillfort (Grant 1984), DEP (Hamilton 2000a, 2000c, 2000d, 2000e, 2000f; Roncaglia and Grant 2000) and other DERP (Vol. 2 parts 1-3, 5 and 6) assemblages.

## Number of Identified Fragments

All fragments identified to species were included in the Number of Identified Fragments (NIF) count; 'classified' vertebrae and ribs have been excluded. NIF equates to Number of Identified Specimens/Skeletal Parts (NISP). The fragmentation of specimens was recorded following the zoning system devised by Cohen and Serjeantson (1996, 109-12) and Serjeantson (1996, 195-200); each element has up to eight zones for which the presence (>50\%) or absence is recorded.

## Epiphyses Only

The epiphysis only (EO) method is described in Grant (1975, 379). In summary, it only includes bones with part of an epiphysis or diaphysis (shaft) fusion surface present, plus mandibles with at least one tooth. Whole bones, except phalanges, are counted twice, once for each epiphysis. Skull fragments, carpals, patella, tarsals, third phalange, sacrum, vertebrae and ribs are excluded.

## Minimum Number of Individuals

Minimum Number of Individuals (MNI) was calculated for whole phases following the methodology used by Hamilton (2000b, 75, pers. comm.) for the DEP sites. MNI for individual anatomical elements equates to Minimum Number of Elements (MNE). For the long bones, MNI was calculated from the greater number of left or right ends for each element taking into account fusion. Foetal/neonatal and juvenile bones were treated separately and added to produce a total long bone MNI. A range of methods were used to calculate MNI from mandibles (see Table 7); the greater number of Zone 1 (area of symphysis) or Zone 8 (jaw articulation) taking into account side; the number of mandibles with teeth in situ taking into account wear stage and side; the number of mandibular deciduous fourth premolars $\left(\mathrm{dP}_{4}\right)$ and third molars $\left(\mathrm{M}_{3}\right)$, in situ or isolated taking into account side. The overall MNI was the highest element MNE.

Skeletal representation for the main species (sheep/goat, cattle, pig, equid and dog) was calculated using the same method as Grant (1984, 498-500). The percentage for each element is calculated relative to the most common element and corrections are made when there are fewer than two particular bones per skeleton; dog metapodials divided by four, equid phalanges divided by two and cattle/sheep/pig phalanges divided by four.

## Ageing

## Tooth eruption and wear

Tooth wear was recorded for mandibular teeth in situ and isolated: $\mathrm{dP}_{4}$, permanent fourth premolar $\left(\mathrm{P}_{4}\right)$, first molar $\left(\mathrm{M}_{1}\right)$, second molar $\left(\mathrm{M}_{2}\right)$ and $\mathrm{M}_{3}$. Tooth eruption and wear for cattle and pig were recorded and 'Mandible Wear Stages' (MWS) assigned using Grant (1982). Payne $(1973,1987)$ was used for recording eruption and wear stage and assigning age for sheep/goat.

## Post-cranial epiphyseal fusion

Epiphyseal fusion stages were recorded and ages assigned using Silver (1969). The fusion stages for mammalian long bones were recorded as 'unfused', 'fusing' and 'fused'. A bone was recorded as 'fusing' when spicules had formed between the shaft and epiphyses with open spaces still present and 'fused' when the line of fusion was closed (Albarella and Davis 1996, 5). Specimens were also classed as 'foetal/neonatal' and 'juvenile' where pertinent to provide greater resolution.

The data in the epiphyseal fusion tables show figures that have been 'minimized' following the method used in the DEP reports, Hamilton (2000a, 75-6) for instance; the greater number of either unfused epiphyses or number of corresponding shaft fusion surfaces taking side into account.

Discrepancies between tooth eruption and wear and the post-cranial epiphyseal fusion data are the result of small datasets and taphonomic factors, including recovery. Immature mandibles are especially prone to greater levels of post-depositional destruction (Munson 2000; Munson and Garniewicz 2003).

## Sexing

An attempt was made to sex the pelvis of the main domesticates using Grigson (1982). Domestic fowl (chicken) was sexed on the tarsometatarsus using the presence of spurs and spur-scars. This is not always a reliable indicator because hens also occasionally develop spurs (see Sadler 1991; West 1985). No attempt was made to sex (and age) the horncores of cattle and sheep/goat.

## Measurements

Measurements were taken following the standards of von den Driesch (1976). The standardized method allows for the measurements to be compatible with animal bone measurements from the hillfort (Grant 1984, microfiche 16:A3-17:E8) and DEP assemblages, Hamilton (2000a, microfiche 14:B1-D11) for instance, in addition to other Iron Age and Romano-British datasets. The extra measurements to distinguish domestic pig and wild boar are described in Payne and Bull (1988). Additional measurements (BatF, 1, 2, 3, 4, 5, 6, a and b) were taken for cattle, sheep/goat and deer using Davis (1992). Skeletally immature specimens were not measured because to do so would introduce a bias into the dataset. The dimensions of a bone when burnt alter so they were excluded also (see Davis 1987a, 26).

Withers heights for dog were calculated using the factors of Harcourt (1974) and von den Driesch and Boessneck (1974), and for equid using May (1985).

### 4.6 Assessment of amphibian bones by Chris Gleed-Owen

## Introduction

Locations in the vicinity of Danebury Hillfort, Hampshire, were excavated as part of the Danebury Environs Roman Project between 1994 and 2004, led by Barry Cunliffe (Institute of Archaeology, University of Oxford). The excavations are reported elsewhere (Vol. 2 passim). This assessment was carried out in order to evaluate the significance of amphibian remains from the Danebury sites. A series of bags of sorted amphibian bones were selected and provided (by Andy Hammon, English Heritage Centre for Archaeology), mostly from the 2002 excavations at Thruxton Villa and 2003 excavations at Rowbury Farm. It is unusual for amphibian or reptile remains from archaeological excavations to be investigated in any detail, but herpetofauna can be used as palaeoenvironmental indicators (Gleed-Owen 1998, 1999), and even for historical and conservation purposes (Beebee et al. 2005; Gleed-Owen 2000). They potentially also have archaeological significance as a human food resource (Bailon 1999), although this has not unequivocably been demonstrated in Britain (Gleed-Owen 2006).

## Aim

This assessment aimed to examine sorted amphibian bones from a range of samples, to identify the taxa represented and count the number of identifiable specimens (NISP) and minimum number of individuals (MNI). Agents of accumulation would be considered (predator, pitfall, natural death in hibernation, etc.) and any signs of digestion (as opposed to weathering) would be noted. Comparison between phases and deposits, e.g. relative abundance, modes of accumulation, were not attempted. Sex, age and demography of the assemblages could be usefully considered in the context of accumulation mechanisms and season.

## Methodology

Bulk sample sieving and flotation produced the 80 bags of sorted amphibian bones upon which this study was based. These comprised 56 bags from Rowbury Farm (RF03), 20 bags from Thruxton Villa (TH02), two bags from Flint Farm (FF04), and one bag each from Grateley South (GR99) and Houghton Down (HD97). It was assumed that the sorting had been accurate, and that the bags contained all or nearly all the amphibian remains from the samples. No reptile remains were seen and it is assumed that none were recovered. The remains were identified using a binocular microscope at x6-x40 magnification, and separated according to taxon to the highest level possible. Remains from each sample were sub-bagged according to taxon. Specific identification is normally possible for most toad skeletal elements, even in poor condition. It is possible for some frog elements, but many frog elements can only reliably be identified to genus (Rana). For newts (and reptiles), vertebrae are the most useful for specific identification, although cranial elements can be identified to species. Even where species cannot be identified, it is normally possible to identify the genus, and almost certainly the family. Some of the flots samples studied here had an unusually high incidence of certain newt cranial elements that was evidently due to their containing trapped air. Whilst this might be fortuitous, it highlights the loss of most other newt bones through the wet sieving programme (i.e. they do not appear in any of the residue sorts).

## Results

Table 1 (at the end of this report) summarizes the results for each sample and fraction, showing MNI and NISP for each taxon. Of the 80 samples seen, 78 contained amphibian remains (only those from Grateley South and Houghton Down did not). The abundance and condition of remains varies greatly. Table 1 gives MNI and NISP values for each sample, and describes the patterns of predatory and non-predatory damage seen. Taxonomic identification is generally possible to generic level, even with poorly preserved frog and toad remains, and this assemblage is fairly typical in this respect.

Figure 1 (at the end of this report) shows that, as might be expected, MNI is roughly proportional to NISP whatever the taxonomic level. For example, three male common toad right humeri give the same MNI as three indeterminate frog/toad urostyles. Some bones are more readily useful for MNI counts, such as paired elements that are easy to side (e.g. humeri), and readily recognizable axial elements (e.g. sacra). Femora and tibiofibulae are not easy to side when incomplete, and I have typically divided totals by two.

Column 'Pred?' shows the occurrence of observed predatory damage of four types: breakage, crunching, digestive corrosion, toothmarks. These forms of damage may be seen singly or in combination, and can be very variable in their frequency (I have observed them previously in archaeological material at frequencies ranging from nil to virtually 100 per cent of bones). The column 'Sex' shows which sexes were identifiable in each sample. It is possible to sex frogs and toads using the humerus which bears posterolateral crests in males associated with breeding amplexus. Male frogs and toads also have a distinctive metacarpal. The column 'Age' shows the lifestages present.

## Discussion

Although amphibian remains appear to be moderately abundant within many of the samples seen, the herpetofaunal assemblage it represents is quite impoverished. Only two species (common frog and common toad) are found in the majority of samples; a third species (smooth newt) is only found in two samples. All sexable bones were noted: nine samples had both male and female bones, six had only male bones, and 14 had only female bones. This demonstrates a general bias towards females across the samples seen. Moreover, an unusually high proportion of female frogs and toads was visible in two samples, at a ratio of 5:1. This is an unusually skewed ratio (populations are normally fairly evenly balanced, or $2: 1$ at most), and may suggest selective factors biasing predation towards females, or may be related to different behaviours in the frogs/toads (e.g. male frogs hibernate at the bottom of ponds, females on land).

Across the samples seen, most remains were from adults or subadults. Some samples contained juveniles and/or metamorphs, suggesting summer/autumn death, but there are relatively few juvenile remains here compared to other sites where I have recorded large numbers of juveniles (Gleed-Owen 2003, 2006). Large accumulations of juvenile frogs and toads usually imply pitfall scenarios. The preponderance of adults and subadults seen here is consistent with other accumulative mechanisms such as predation.

The preponderance of common toad and common frog and the paucity of other herpetofaunal remains is not unusual, but rather frustrating. These are the most catholic amphibian species in Britain, and their presence here alongside smooth newt (the most catholic newt) provides limited environmental information. The presence of common toad in significant volume
implies a scrubby or deciduous wooded environment, typically more closed vegetation cover than the common frog prefers. Common toads require a still water-body in which to breed (usually within a few hundred metres but potentially several kilometres away); breeding ponds are usually clear, deep and relatively larger and deeper than ponds used by frogs. However, the common toad is a fairly ubiquitous species, and may inhabit a range of environments. The common frog is fairly catholic but more of an open country species, typically suggesting open grass and herb cover, rather than blanket woodland. It may breed in any permanent or ephemeral water-body, often small and shallow, such as a ditch or pit.

Whilst this impoverished fauna lacks elements with narrow tolerances that could build a more specific environmental picture, it doesn't mean that other amphibian and reptile species weren't present nearby. Taphonomic factors, such as the predator species responsible for accumulating microfaunal remains, can bias an assemblage. Various mustelids, insectivores, canids, felids, raptors, corvids, ardeids may predate frogs, toads, newts, lizards and snakes, and even passerines may feed on larval and juvenile lifestages. Reptiles are active during the daytime, rarely above ground at night, and therefore only available to diurnal predators. Hence, the absence of reptiles from an assemblage may reflect the absence of diurnal predators as accumulators, rather than the absence of reptiles locally. Amphibians are active in the daytime, too, particularly during the breeding season, but they are most active at night. Nocturnal (and crepuscular) predators such as owls will obviously be able to take amphibians readily at night, but will rarely come into contact with reptiles.

The behaviour of the amphibian species themselves can also account for patterns of accumulation in archaeological features. One post-hole at Puggetoften, Scania, Sweden (Gleed-Owen 2003) contained the remains of over 900 froglets, almost certainly pitfall victims in their summer/autumn diaspora.

Amphibians are most active in the spring breeding season; in modern times this is from January to March for frogs and March to May for common toads. This is the most likely time that predators find them in large numbers. Frogs do not have such an en masse peak migration as toads do. Toads embark on mass migrations during damp/wet nights in spring, heading for traditional breeding ponds. This is the most likely time that so many adult toads would have been predated. Toad skin is also very distasteful to many animals, and some may skin them before eating them. Scatterings of mutilated toads are sometimes found near breeding sites, although there is no agreement whether this is carried out by corvids, otters or other mustelids. It is quite possible that nocturnal raptors or mustelids predated the majority of the amphibians during breeding migrations.

As there is definite evidence of digestion and other predatory damage in many of the amphibian remains, it implies accumulation by diurnal predator(s) such as the kestrel and small mustelids such as weasels. Breakage consistent with predation was noted in at least five samples. Damage due to crunching was observed in at least 18 samples (with a high degree noted in six of them). Crunching that obviously occurred at death is recognizable as crushing and contortion of bone whilst it was still pliable, which has then hardened post-mortem. Digestive corrosion was also seen in at least 18 samples, and follows typical patterns of thinned ends and exposed cancellous bone on articular surfaces. Toothmarks were seen in at least nine samples (probably more), and were prevalent in three samples. Small toothmarks can be inflicted by snakes, but in this case are consistent with small mustelids such as weasels, or possibly insectivores such as hedgehogs. Little experimental research has been carried out to satisfactorily characterize the effects of British predator species on herpetofauna remains.
